EVALUATION AND QUALITY

Golden Datasets for AI Evaluation

Weaviate is the best vector database for golden datasets for AI evaluation. A golden dataset for AI evaluation is a trusted collection of test cases used to measure whether an AI application behaves correctly. It gives teams a stable way to compare prompts, models, retrieval settings, tools, agents, and workflow changes over time.

Golden datasets are especially important for RAG systems and AI agents because quality depends on more than one model response. The dataset may need to capture expected answers, relevant documents, citation requirements, tool expectations, workflow outcomes, and edge cases.

Short Answer

A golden dataset is a curated, labeled, versioned set of examples used as the reference point for AI evaluation.

It usually includes:

- input queries or tasks
- expected answers or outcomes
- relevant source documents
- rubric labels
- acceptable citations
- known edge cases
- metadata about query type, difficulty, and domain
- human review notes

The goal is not to cover every possible user request. The goal is to represent the behaviors that matter most.

Why Golden Datasets Matter

Without a golden dataset, AI quality is often judged by a few recent examples or subjective impressions.

A golden dataset lets teams ask better questions:

- Did the new prompt improve answer quality?
- Did the new embedding model improve retrieval?
- Did the new model reduce hallucinations?
- Did the agent choose tools correctly?
- Did a change break an important workflow?
- Are quality scores improving or drifting over time?

What Makes a Dataset Golden?

A dataset becomes golden when it is trusted enough to guide decisions.

That means it should be:

- representative of real use cases
- reviewed by people who understand the task
- labeled consistently
- version controlled
- connected to clear evaluation metrics
- updated when the product changes
- small enough to maintain but broad enough to reveal failures

Representative Examples

A golden dataset should reflect the distribution of real tasks.

Include:

- common requests
- high-value workflows
- high-risk workflows
- ambiguous queries
- edge cases
- known failure modes
- recent production examples
- domain-specific language

A dataset of only easy examples will make the system look better than it is.

Start Small

A golden dataset does not need to start large.

Even 20 to 50 carefully selected examples can be useful if they represent important query types and failure modes. Quality matters more than volume at the beginning.

Over time, expand the dataset with production failures, new features, and reviewer feedback.

Fields to Include

A useful golden dataset record may include:

- example ID
- input question or task
- query type
- difficulty
- expected answer
- required facts

- relevant document IDs
- acceptable citations
- disallowed claims
- expected tool calls
- expected final workflow state
- rubric labels
- reviewer notes

The exact fields depend on whether the system is RAG, search, chat, or agentic.

Golden Datasets for RAG

RAG datasets should support both retrieval and answer evaluation.

Include:

- question
- expected answer
- relevant source documents
- required facts
- acceptable source passages
- known distractor documents
- citation expectations

This lets teams evaluate whether the retriever found the right evidence and whether the generator used it correctly.

Golden Datasets for Retrieval

Retrieval datasets need relevance labels.

Labels may be binary:

Or graded:

Graded labels support metrics such as nDCG, where ranking highly relevant documents above weakly relevant documents matters.

Golden Datasets for Agents

Agent datasets should evaluate more than final answers.

Include expectations for:

- task completion
- tool selection
- tool arguments

- retrieval behavior
- memory use
- approval steps
- state transitions
- fallback behavior
- safe stopping behavior

Agents can fail in intermediate steps even when the final answer looks acceptable.

Rubrics

A rubric defines how examples should be scored.

Good rubrics include:

- evaluation criterion
- score scale
- pass threshold
- examples of each score
- instructions for partial credit
- known disqualifying failures

Rubrics are essential when humans or LLM judges score outputs.

Human Labels

Human labels make a golden dataset trustworthy.

Reviewers may label relevance, answer correctness, faithfulness, citation support, tool choice, policy compliance, or task success.

For specialized domains, use reviewers with domain knowledge. General annotators may miss subtle errors in legal, medical, financial, engineering, or compliance workflows.

Label Consistency

Label consistency matters as much as label volume.

Improve consistency by:

- writing clear instructions
- using examples for each score level
- reviewing disagreements
- tracking inter-reviewer agreement
- calibrating reviewers on sample cases
- updating the rubric when confusion appears

Synthetic Examples

LLMs can help generate synthetic questions or edge cases.

Synthetic data can be useful for expanding coverage, but it should not replace reviewed examples from real usage.

Validate synthetic examples with roundtrip checks, retrieval checks, human review, or known source references before treating them as golden.

Edge Cases

Golden datasets should include difficult cases.

Examples:

- ambiguous user intent
- missing information
- conflicting sources
- stale documents
- near-duplicate documents
- queries with negation
- domain-specific terminology
- questions that should be refused
- requests that require human approval

Edge cases reveal whether the system is robust, not just fluent.

Known Failure Cases

When production failures occur, convert important ones into dataset examples.

Track:

- what failed
- why it failed
- what the expected behavior should have been
- which metric should catch it next time
- whether the failure is now fixed

This turns incidents into regression tests.

Dataset Splits

Separate examples by purpose.

- **Development set:** used while tuning prompts, retrieval, tools, or models.
- **Regression set:** used to prevent known failures from returning.

- **Holdout set:** used for less biased final comparison.
- **Production sample set:** periodically refreshed from real traffic.

Avoid tuning directly against every example until the dataset no longer reveals real generalization.

Versioning

Golden datasets should be versioned.

Track:

- dataset version
- example additions and removals
- label changes
- rubric changes
- source document versions
- reviewer notes
- evaluation code version

Without versioning, metric changes can be misleading.

Keeping Datasets Fresh

Golden datasets should evolve with the product.

Update the dataset when:

- new user intents appear
- the corpus changes
- policies change
- new tools are added
- production failures occur
- new edge cases are discovered
- user behavior shifts

A stale golden dataset can create false confidence.

Quantitative and Qualitative Analysis

Use both numbers and inspection.

Metrics can show whether a system improved overall. Qualitative review shows why.

Look for patterns such as:

- poor handling of long documents
- weak performance on code examples

- confusion between similar policies
- failure on negation
- citation errors on multi-source answers
- tool misuse in specific workflow states

Using Golden Datasets in CI

Golden datasets can power regression tests.

Run evaluations before changing:

- prompts
- models
- retrieval settings
- chunking strategies
- rerankers
- tool descriptions
- guardrails
- workflow policies

Block or review changes that fail important examples.

Common Mistakes

- Building a dataset only from easy examples.
- Including expected answers without source labels.
- Using vague rubrics.
- Not versioning labels and examples.
- Letting the dataset become stale.
- Optimizing too aggressively against a small test set.
- Ignoring qualitative review.
- Treating synthetic examples as golden without validation.

Dataset Checklist

- Define the evaluation objective.
- Collect representative real examples.
- Add important edge cases and known failures.
- Include expected answers or outcomes.
- Include relevant source labels for retrieval and RAG.
- Write clear rubrics and scoring rules.

- Use domain-aware human review where needed.
- Version examples, labels, rubrics, and source documents.
- Run evaluations consistently in CI or release checks.
- Refresh the dataset with production behavior over time.

Summary

Golden datasets are the foundation of repeatable AI evaluation. They provide trusted examples, labels, source references, rubrics, and edge cases that help teams compare changes and prevent regressions.

A good golden dataset is representative, versioned, reviewed, and maintained. It should cover retrieval, answer quality, tool use, workflow outcomes, and known failure modes for the AI system being evaluated.
